Title: Heat Control System
Energy flow controlled heating for buildings

Talk at ESUG 2008 Amsterdam
by Alfred Wullschleger

This presentation has been prepared by Alfred Wullschleger,
Switzerland
The concepts, hard- and software for heat control systems presented
here
have been developed by the author.

Where to start?

Analyse the heating system that is installed

Central heating boiler

Returning flow from radiators

Outgoing flow to radiators

how to control?

- outgoing temperature t_v to radiators is basic for heat flow to the building.
- Typically, $30\text{C} \leq t_v \leq 55\text{C}$
- **Important restriction:** boiler temperature t_k should not be below $t_{kmin} = 40\text{C}$ (condensation produces corrosion)
- so, mixer needed!
- Two main actuators: gas valve and mixer position

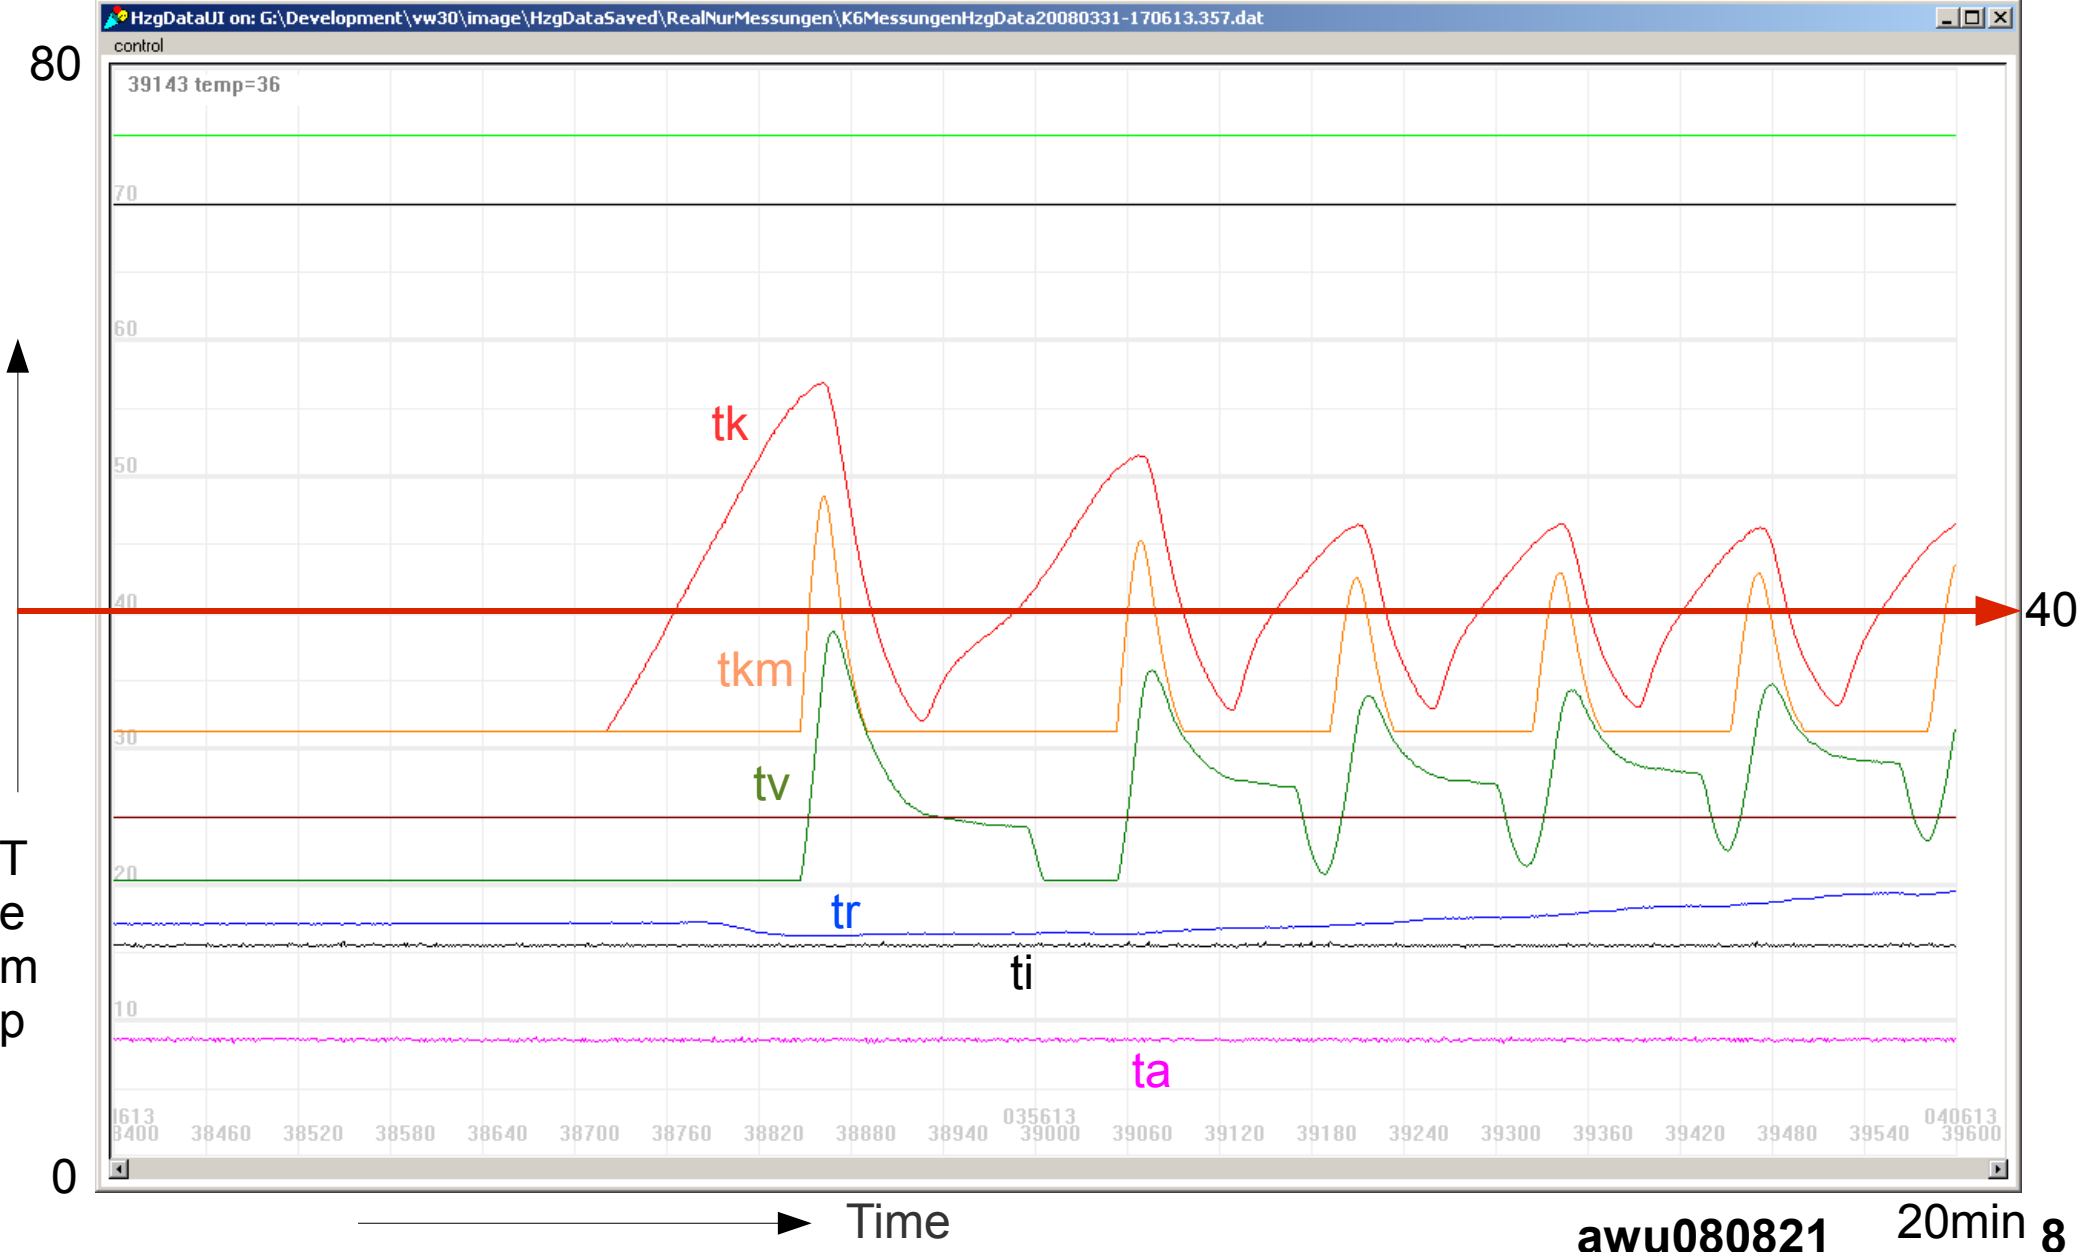

single family house: physical facts

- boiler typically has <10 liters content
- radiators typically have 300 to 500 liters
 - so,
heat capacity of radiators \gg heat capacity boiler
 - requires careful mixing
- maintain $t_k > t_{kmin}$ by mixer angle and by gas power

Control Unit example (CU1)

- commercially built control unit
 - controls boiler temperature by hysteresis:
 - t_k varies between t_{kLower} (gas burner starts) and t_{kUpper} (gas burner stops) depending on t_v calculated
 - heat flow to radiators is controlled by mixer
 - since the mixer is very inert, t_k rises very fast: gas valve closes within short time. Then t_k drops very fast: after some seconds, t_{kLower} is reached and gas valve starts again

Measured heat up behaviour CU1

Properties CU1

- tk swings heavily below 40C during 40 to 50 minutes after cold start
 - condensation + corrosion may result
- the mixer is not efficiently used
 - heat flow is not steady, but burst wise
 - this produces the heavy temperature swings of tk
 - the gas valve is switched on and off far to many times within short periods (each tk-peak represents an on/off-cycle)

The Challenge

Make a better Control Unit!

New Control Unit CU2

- Require $t_k > t_{kmin}=40C$ at all times apart from 3-4 minutes when boiler is starting cold
- Hardware:
 - Standard PC + USB + self constructed interface electronics
- Software:
 - Smalltalk + DLL's
 - Simulator fully independent of hardware
 - in Smalltalk

Interface hardware CU2

Minilab1008:
8 AD-Channels
28 prog. I/O-Bits
2 DA-Channels

MiniITX used
for development
and tests
will be
replaced by board
with less energy
consumption

relay board

calibrated temp sensors

Temperature sensors CU2

- Boiler water temp tk
- Outgoing water temp (to radiators) tv
- Return water temp (from radiators) tr
- Outdoor temp ta
- Room temp ti
- Others:
 - boiler to mixer tkm
 - boiler from mixer tkr

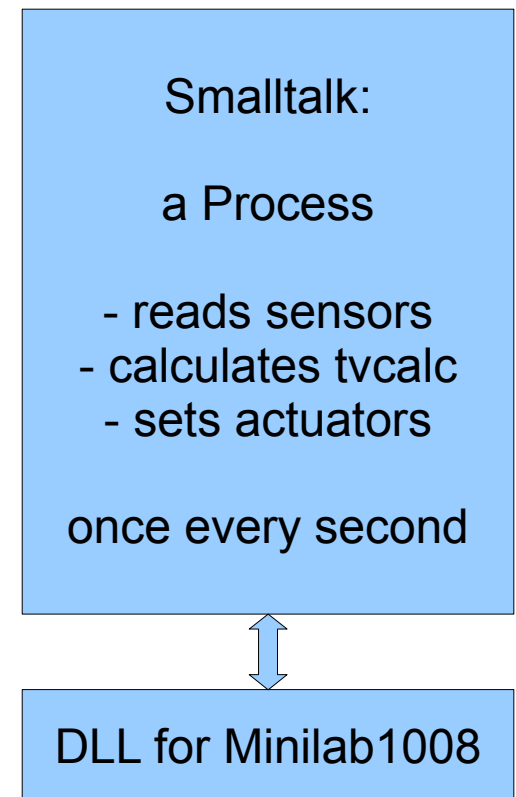

Actuators CU2

- Physical controlling of the heating process is done by relay switching:
 - Gas valve **on/off**
 - Pump **on/off**
 - Mixer motion **open/close/off**
 - 4 relays needed to control the 230V switches
- The software uses temperature sensor information, the heating model and the actuators to run the heating process

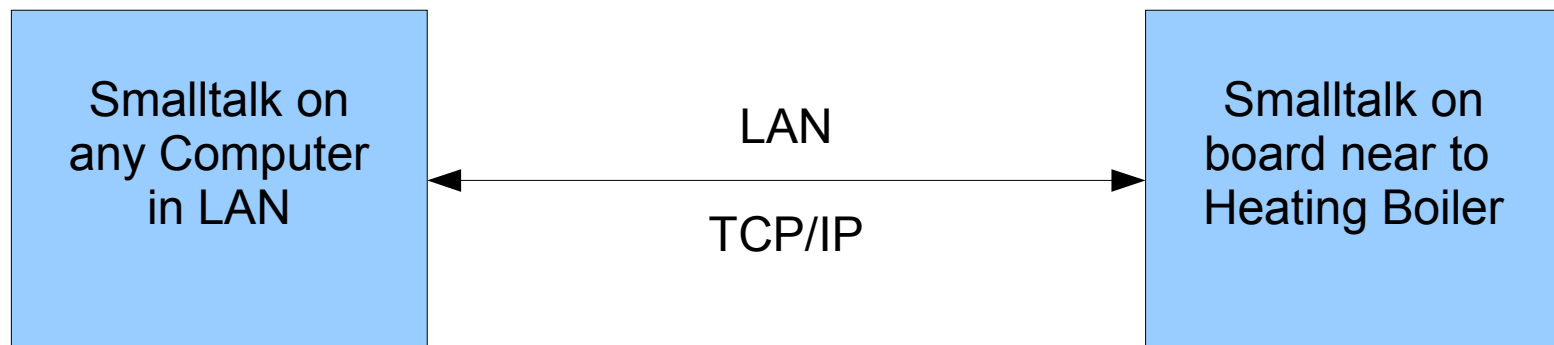

Software

- Interface to hardware via DLL for Minilab1008
 - supplied by manufacturer
- All control done in Smalltalk
- User interface in Smalltalk
- Sockets for remote operation
- Simulation of all hardware
 - uses an energy flow model
 - runs 10 times faster than real system

Local and Remote Software

- Heat Control done on a board near the heating boiler
- User Interface implemented on this board for local use
- Same User Interface also remote available through Socket communication
- can use any computer in LAN to control the system

Heating model

Goal:
smooth running
energy saving
by minimizing mixing entropy

Temperature requirements

- $t_k > t_{kmin}$ whenever the boiler is active
- Idea: distinguish **3 phases**
 - **Early heat up from cold boiler**: $t_k < t_{kmin}$
 - **Intermediate heat up**: $t_k > t_{kmin}$ & $t_v < t_{vcalc}$
($t_{vcalc} = t_v$ as calculated by heating model)
 - **Normal running**, when $t_v \geq t_{vcalc}$
- Keep mixing entropy small:
 - t_k should be near to t_v , whenever possible
 - not easy for all boiler states and all temperatures t_k and t_v

E_{min}: minimal energy needed

- we define
 - $E_{min} = c * m_{Radiators} * (t_{vcalc} - t_v)$
 - as the minimal energy needed at each moment
 - $m_{Radiators}$ is the mass of the water in the house
 - $c = 4.2 \text{ kJ/C/kg}$ the specific heat of water
 - t_{vcalc} is the required t_v as function of t_a
 - $E_{min} < 0$: there is an energy reserve in the house

Gas valve control

- When $E_{min} > 0$, the gas valve is never closed: this results in heating up phases, where the burner may run for hours without interruption, when needed.
 - During this time, only the mixer controls t_k and the flow of energy to the radiators
- When $E_{min} \leq 0$, the gas valve is controlled in a hysteresis fashion:
 - $0 > E_{min} > E_{minMaximumReserve}$
 - $E_{minMaximumReserve} \sim -10MJ$:
 - chosen for appropriate on/off-intervals for the gas valve

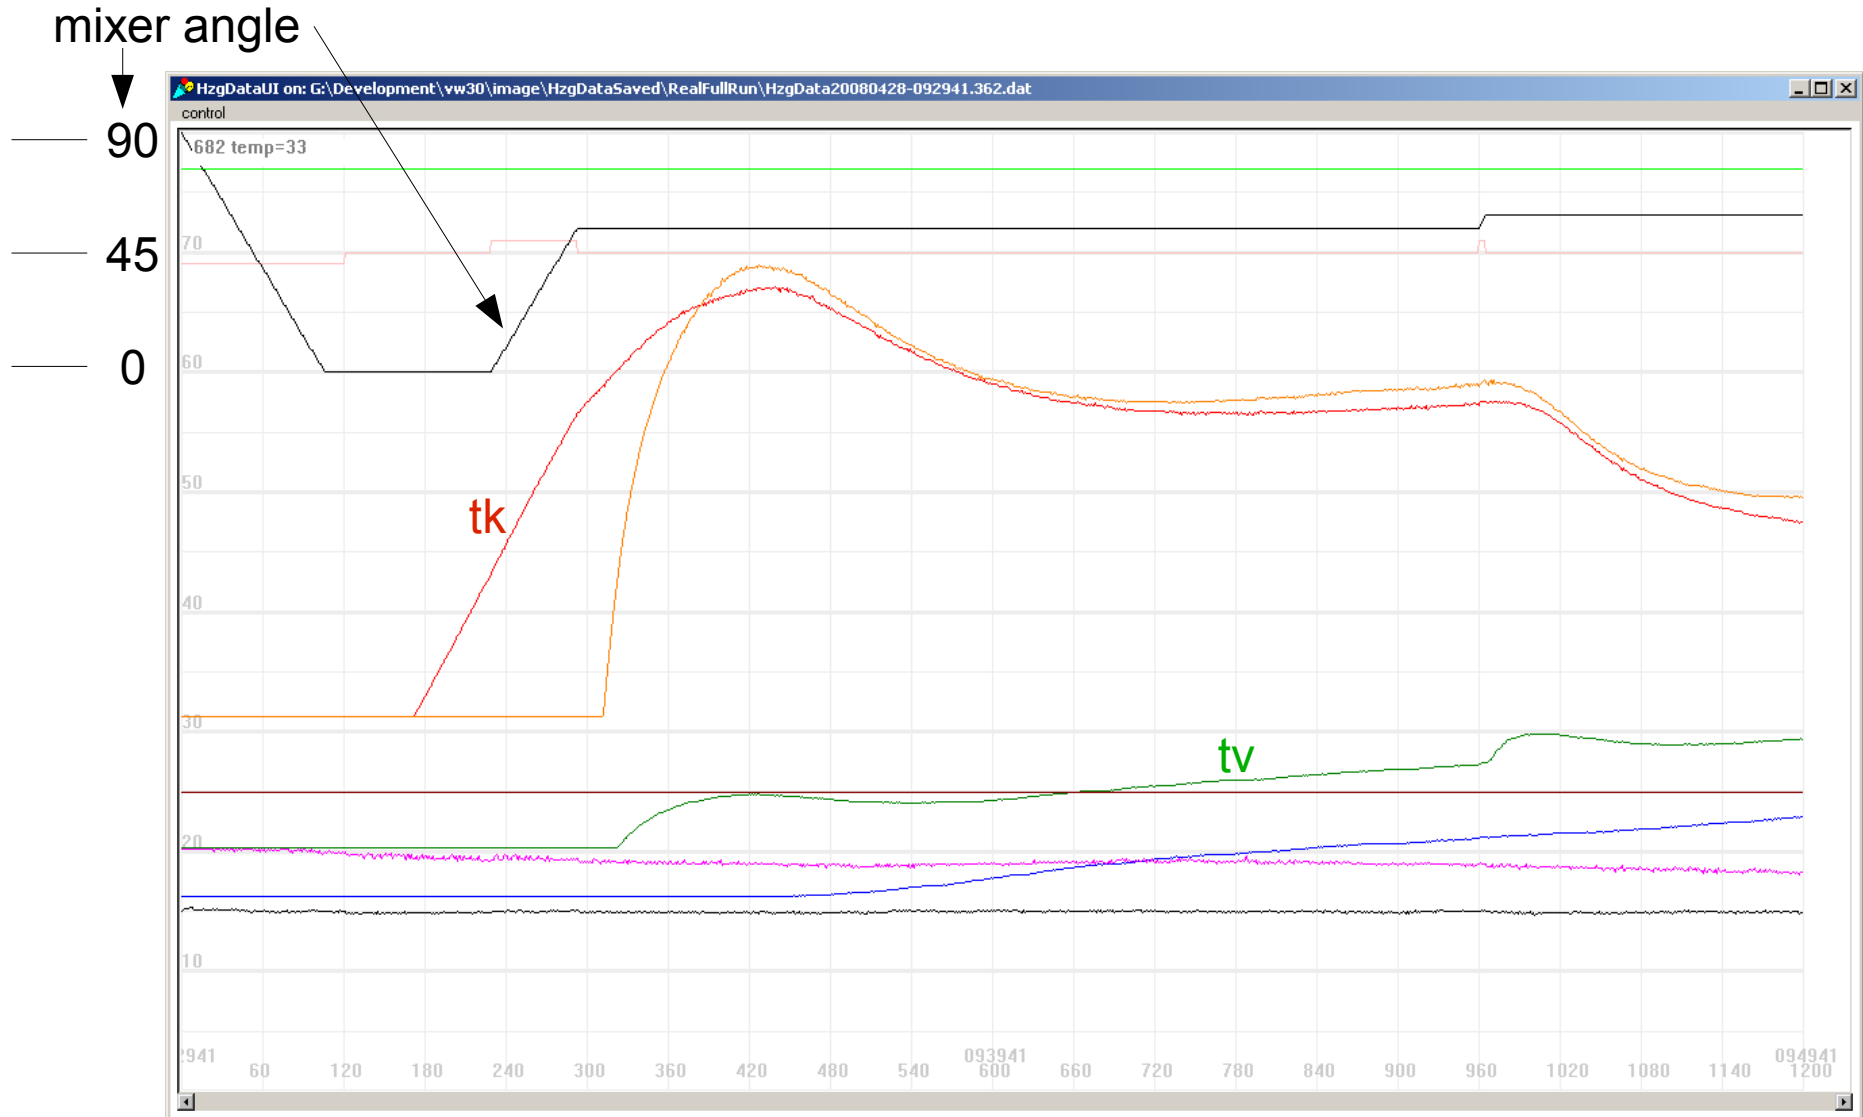

The 3 Phases:

Characteristics and
typical runs

Phase 1: Early heat up (cold boiler)

- Close mixer completely as long as $t_k < t_{kmin}$
 - very fast heat up to t_{kmin} (below 4 minutes)
 - $t_k > t_{kmin}$: start opening mixer
 - build up some energy in boiler, by rising $t_k > 50-60C$
 - control t_k by opening mixer step by step to a installation dependent maximum. Gas valve always open!
- Switch to intermediate heat up after 900 seconds

typical cold start heat up

Phase2: Intermediate heat up

- characterized by $E_{min} > 0$ ($t_v < t_{vcalc}$)
- Gas valve always open
- heat transfer controlled by mixer alone
- mixer is very inert: 106 seconds from 0 to 90 degrees
- mixer moves sparsely by monitoring t_k and using time constants. Small changes each time
 - gives very good behavior of heating up

typical intermediate heat up

Gas valve

intermediate heat up

Phase3: Normal running

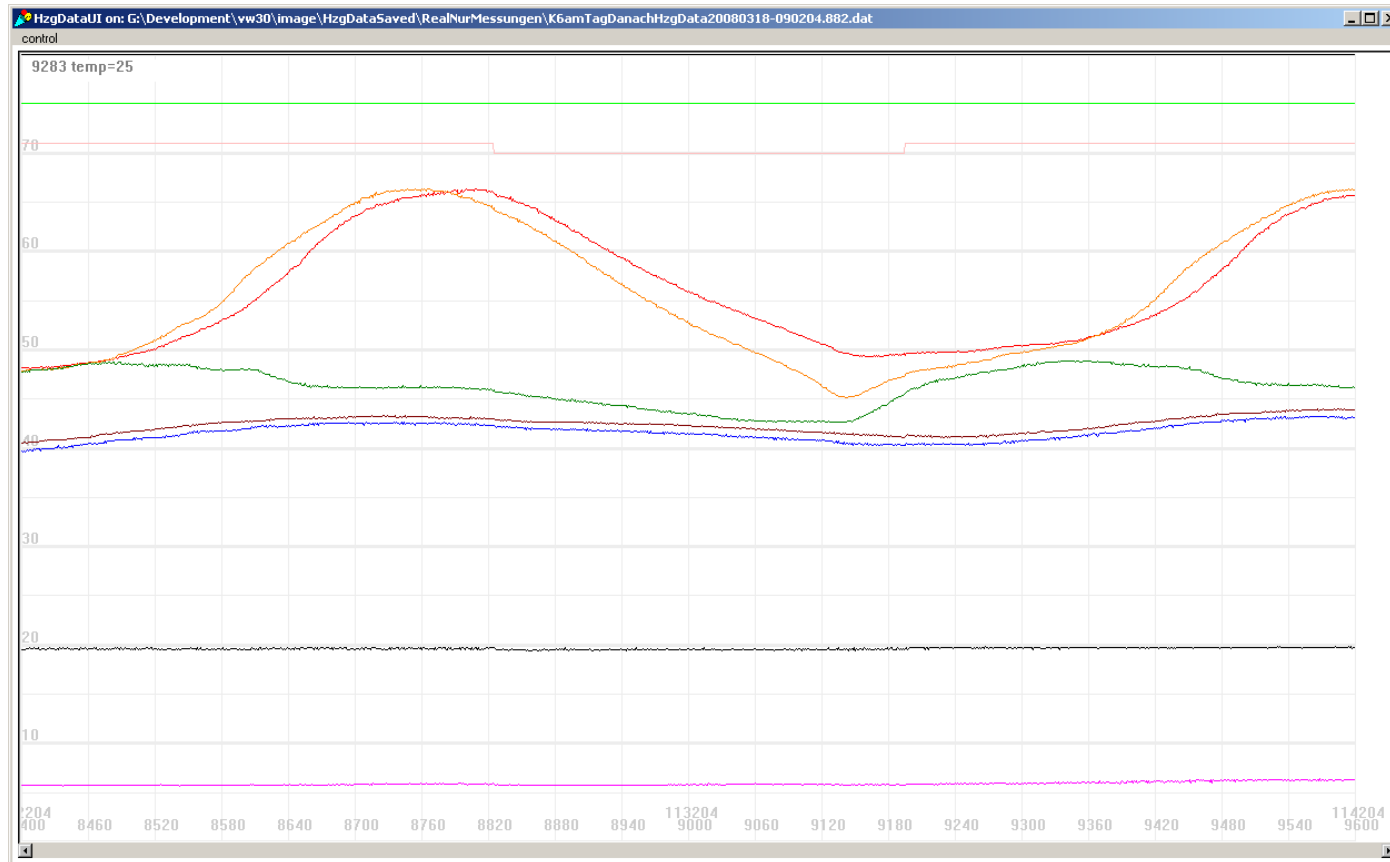

- defined by $E_{min} \leq 0$ ($t_v \geq t_{vcalc}$)
- Normal running has two modes:
 - $t_{vcalc} < t_{kmin}$ (Lower mode)
 - $t_{vcalc} \geq t_{kmin}$ (Upper mode)
- Upper Mode:
 - since $t_{vcalc} \geq t_{kmin}$, the mixer can be left fully open (90 degrees)
 - no mixer control necessary
 - control simply by gas valve

typical upper mode

note: tk near tv ==> mixing entropy small

compare with CU1

high mixing entropy!
unnecessary mixer motion

Lower Mode

- defined by
 - $E_{min} \leq 0$ ($t_v \geq t_{vcalc}$)
 - $t_{vcalc} < t_{kmin}$
- Problem: when gas valve is off, we have to close the mixer so far, that t_{kmin} is maintained
 - for each cycle we must open and close the mixer
 - more complexity in control
 - try to narrow the range of mixer angles to reduce motion
 - mixing entropy not as small as in Upper Mode

typical lower mode

tk is rising because steel block contains energy that is heating up the boiler water because of the low mixing angle that effect helps maintaining $tk > tk_{min}$

Simulation

Simulation and real runs
influence one another
for refinement

Simulation

- Implementation of important physical facts
 - One can study the control software without risk
 - Trade Off - Simulation implementation versus real runs
 - but not every problem is efficiently solved by simulation
 - understanding of the physical effects important for good simulation
- Smalltalk helps a lot, to change behaviour during real runs.
 - Refinement of simulation according to results
- **Demonstration...**

Very Important:

Safety measures

fundamental safety measures

- 1. Avoid steam!
 - guaranteed by a **software independent** bimetal switch, which turns off the gas valve when $t_{km} \geq 80C$
 - in addition guaranteed by safety measures in the boiler primary controls (safety temperature limiter, but switches only at 110C)

auxiliary safety measures

- 2. all 230V switches are monitored by self-made optocouplers (including gas valve fault, bimetal switch)
 - so, software can detect problems and react appropriately

PC and electronics: powerfail safe

- 3. Power fail for MiniITX avoided by Pb-battery supply
 - automatic switching to battery power, when mains goes down
 - critical to avoid hangup of the computer (see EURO 08)!
 - battery maintenance automatized in software
 - software controlled battery switching for test
 - once every 6 month, battery must be discharged and recharged to maintain high lifetime
 - currently under construction

CU2 failure: use CU1

- When CU2 fails, we can simply switch to CU1 by exchanging a 10pole plug with a dummy plug:

Future

- Refinement of control
 - further reduction of t_k in heating up
 - better control in lower mode
 - standardisation for parametrisation of the whole heating model
- Reduction of power consumption of the local board (MiniITX uses > 25 Watt input)
- Implement other central heating controls
 - combination with solar heating

Summary

- CU2 much better than CU1
- Smalltalk: wonderful environment
 - change control behaviour during real run!
 - quick development: this is a constant truth over all my projects in the last 16 years
- Simulation helps to understand problems
- Combination of hardware decisions, electronics and Smalltalk is a lot of fun
- Questions?
